- Policy Gradients

# Supervised Learning

**Data:**  $(x, y)$

$x$  is data,  $y$  is label

**Goal:** Learn a *function* to map

**Examples:** Classification, regression, object detection, semantic segmentation, image captioning, etc.

→ Cat

Classification

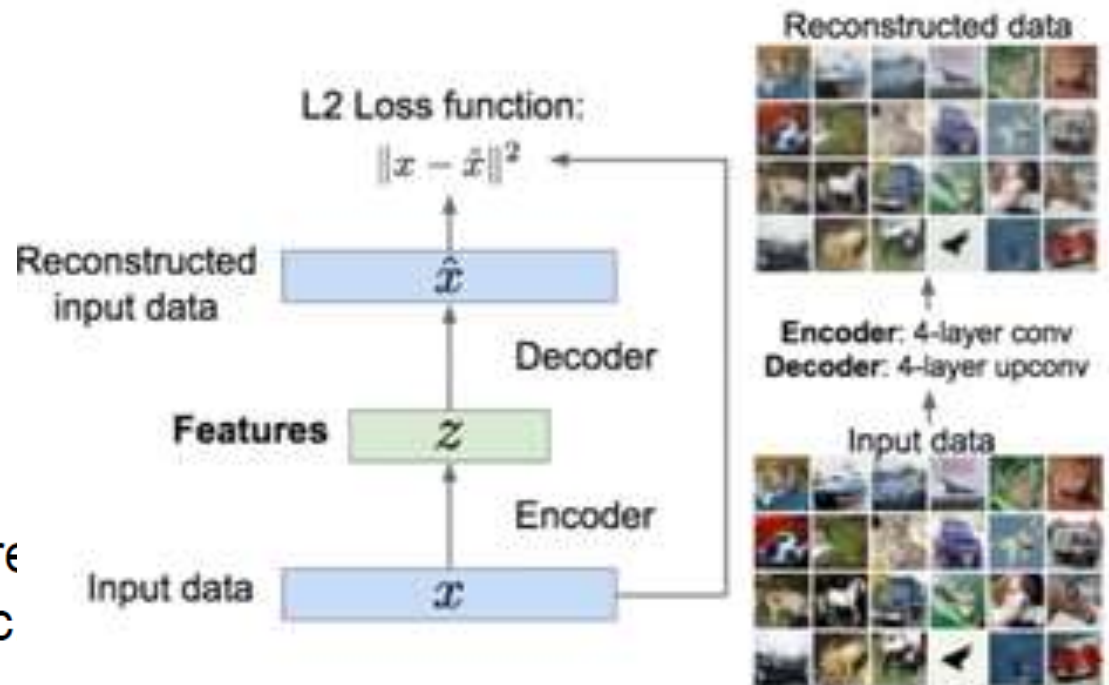

# Un-Supervised Learning

**Data:**  $x$

Just data, no labels!

**Goal:** Learn some underlying hidden *structure* of the data

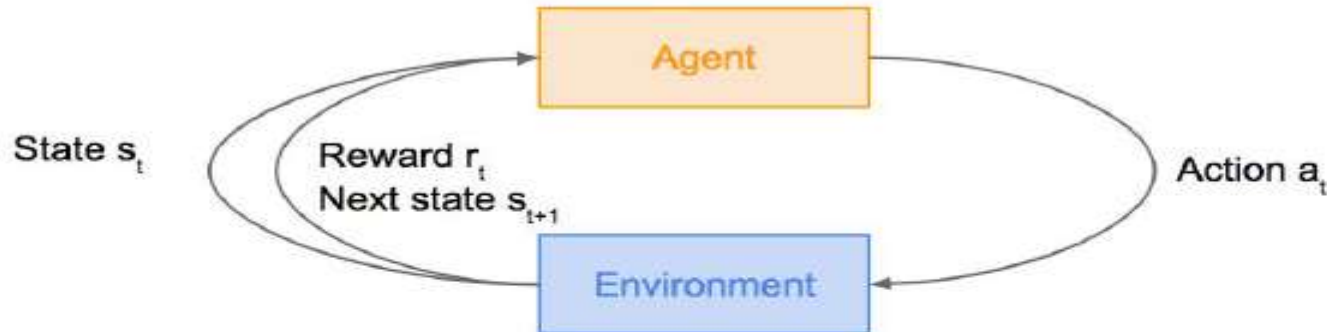

**Examples:** Clustering, dimensionality reduction, feature learning, density estimation, etc

# Reinforcement Learning

Problems involving an **agent** interacting with an **environment**, which provides numeric **reward** signals

**Goal: Learn how to take actions** in order to maximize reward

# Reinforcement Learning

Agent

```
graph TD; Agent[Agent] --- Environment[Environment];
```

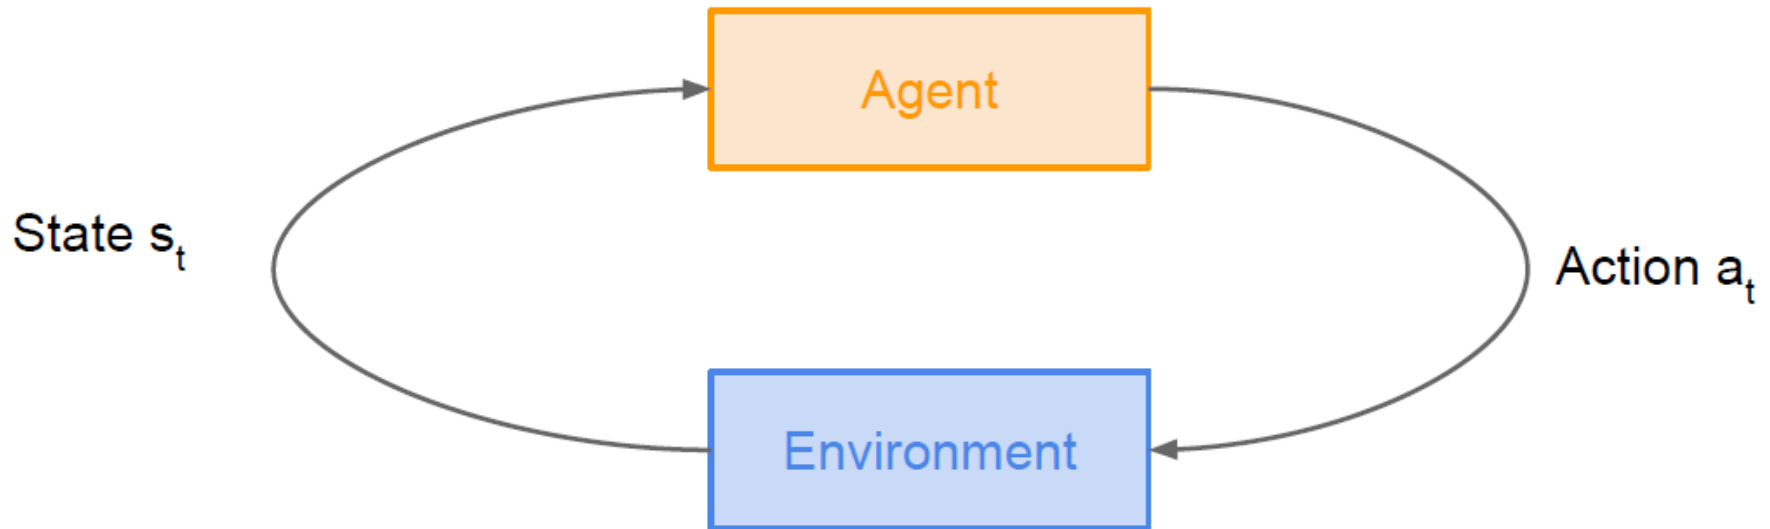

The diagram illustrates the basic components of Reinforcement Learning. It consists of two rectangular boxes. The top box is light orange with an orange border and contains the word "Agent" in orange text. The bottom box is light blue with a blue border and contains the word "Environment" in blue text. The two boxes are vertically aligned and connected by a vertical line, representing the interaction between the Agent and the Environment.

Environment

# Reinforcement Learning

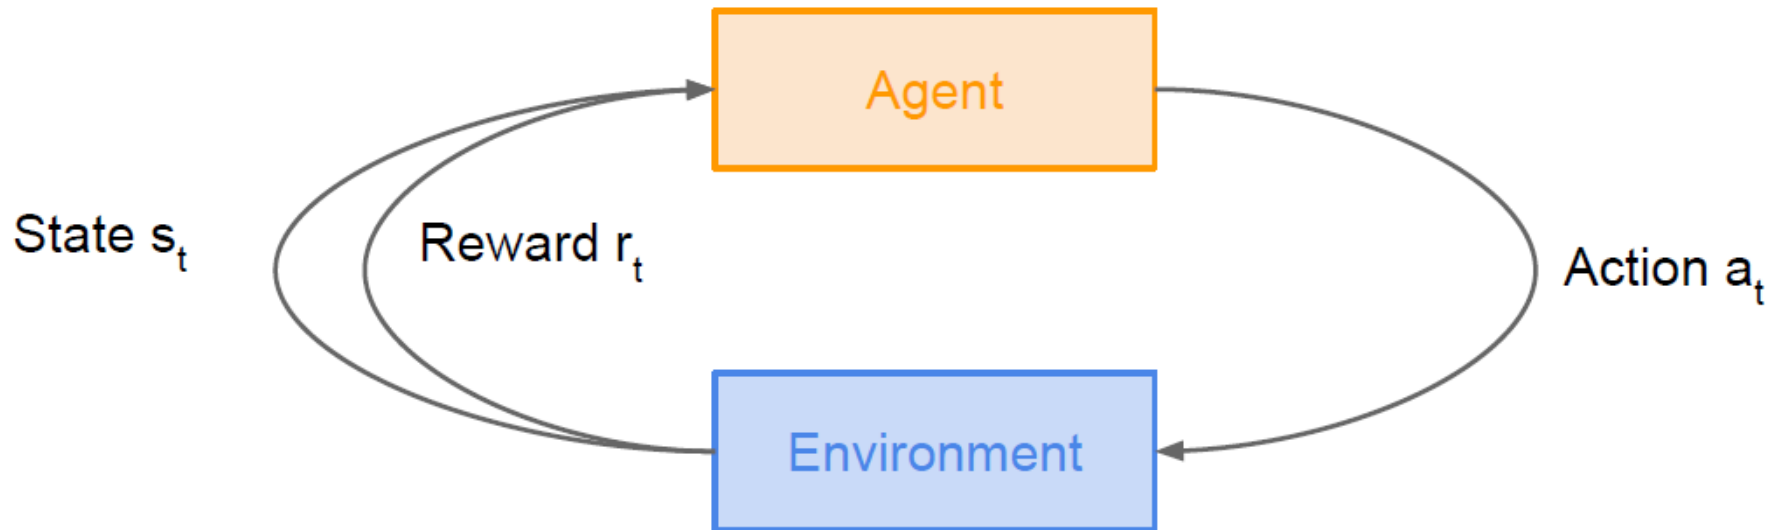

# Reinforcement Learning

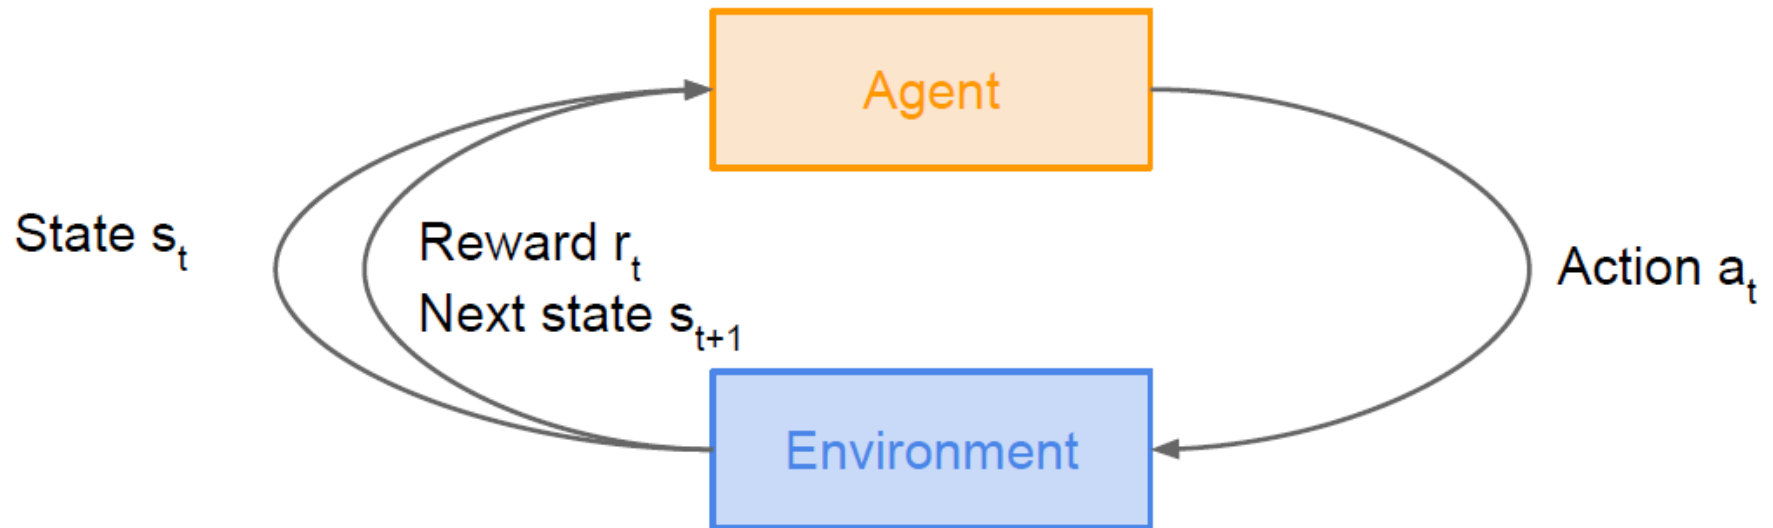

# Reinforcement Learning

# Reinforcement Learning

# Cart-Pole Problem

- Objective** : Balance a pole on top of a movable cart
- State** : angle, angular speed, position, horizontal velocity
- Action** : horizontal force applied on the cart
- Reward** : 1 at each time step if the pole is upright

# Robot Locomotion

**Objective:** Make the robot move forward State: Angle and position of the joints

**Action:** Torques applied on joints

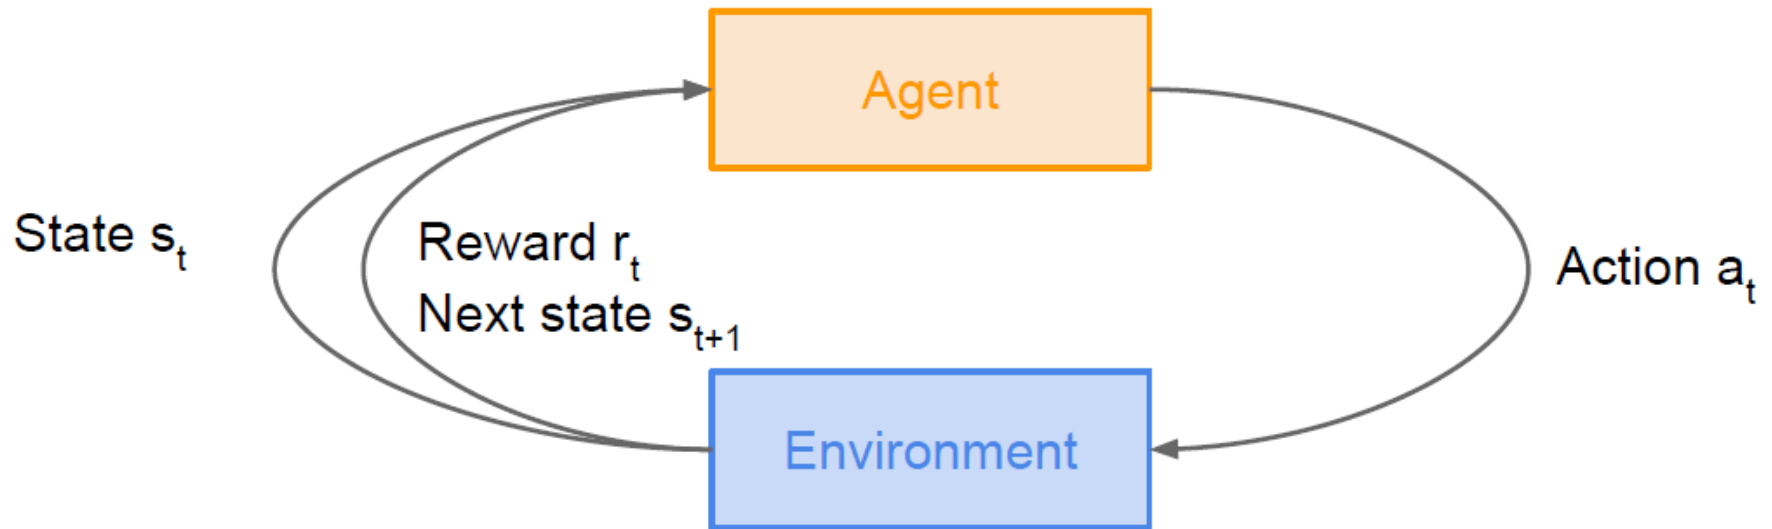

**Reward:** 1 at each time step upright + forward movement

# Atari Games

- Objective** : Complete the game with the highest score
- State** : Raw pixel inputs of the game state
- Action** : Game controls e.g. Left, Right, Up, Down
- Reward** : Score increase/decrease at each time step

# RL: Mathematical Formulation

# Markov Decision Process

- Mathematical formulation of the RL problem
- **Markov property:** Current state completely characterises the state of the world

Defined by:  $(\mathcal{S}, \mathcal{A}, \mathcal{R}, \mathbb{P}, \gamma)$

$\mathcal{S}$  : set of possible states

$\mathcal{A}$  : set of possible actions

$\mathcal{R}$  : distribution of reward given (state, action) pair

$\mathbb{P}$  : transition probability i.e. distribution over next state given (state, action) pair

$\gamma$  : discount factor

# Markov Decision Process

**S** is a set of a finite state that describes the environment.

**A** is a set of a finite actions that describes the action that can be taken by the agent

**P** is a probability matrix that tells the probability of moving from one state to the other.

**R** is a set of rewards that depend on the state and the action taken. Rewards are not necessarily positive, they should be seen as outcome of an action done by the agent when it is at a certain state. So negative reward indicates bad result, whereas positive reward indicates good result.

**$\gamma$**  is a discount factor, that tells how important future rewards are to the current state. Discount factor is a value between 0 and 1. A reward  $R$  that occurs  $N$  steps in the future from the current state, is multiplied by  $\gamma^N$  to describe its importance to the current state. For example consider  $\gamma = 0.9$  and a reward  $R = 10$  that is 3 steps ahead of our current state. The importance of this reward to us from where we stand is equal to  $(0.9^3) * 10 = 7.29$ .

# Value Functions

Now with the MDP in place, we have a description of the environment but still we don't know **how the agent should act in this environment**.

The rule we impose on the agent is that it must act in a way to **maximize the collected rewards**.

But to be able to do that, the agent should have something to estimate the position or state it is currently in.

Consider again the labyrinth, if the agent is few steps from the exit, his position has much more value than a position at the center of the labyrinth.

We call this is to estimate **the Value of the position** or **the Value of the state**.

Once we know the value of each state, we can figure out what is the best way to act (simply by following the state that with the highest value).

# State Value Function

Still we need to figure out a way to quantify the value of each state. This is done by a function called **State-Value Function**:

$$v_{\pi}(s) = \sum_a \pi(a|s) \sum_{s', r} p(s', r | s, a) [r + \gamma v_{\pi}(s')], \quad \text{for all } s \in \mathcal{S}$$

What is important to learn about this equation is that the **value of each state is the average of discounted future rewards**.

If we look closely at the equation we see that  **$v(s)$**  is expressed in terms of **immediate rewards  $r$**  and **the value of neighboring states  $v(s')$** .

# State Value Function

$$v_{\pi}(s) = \sum_a \pi(a|s) \sum_{s', r} p(s', r | s, a) [r + \gamma v_{\pi}(s')], \quad \text{for all } s \in \mathcal{S}$$

1. When at a state  $s$ , consider all possible actions, then,
2. for each action  $a$  get the probability  $p(s', r | s, a)$  of getting immediate reward  $r$ , and moving to neighboring state  $s'$ , knowing that we are at state  $s$  and we performed action  $a$ .
3. Add the reward  $r$  to the discounted value of neighbor state  $s'$  given by  $\gamma * v(s')$ . Multiply the result with  $p(s', r | s, a)$ , and we get  $p(s', r | s, a) * [r + \gamma * v(s')]$ .
4. Repeat steps 2 and 3 for all states  $s'$  neighboring  $s$ , as well as all the possible rewards  $r$ , and compute the sum of the results. Now we have  $\text{Sum}(p(s', r | s, a) * [r + \gamma * v(s')])$  over all  $s'$  and  $r$ .
5. This will give the average of discounted future rewards when taking only one action  $a$ . However there are multiple actions to be taken so we have to average over all actions. To do so we multiply by probability  $\pi(a|s)$  that action  $a$  be performed at state  $s$ , and we sum over all possible actions in that state.

# Action Value Function

- It suffices to think that when we are at a state we have a probability to take some action that might lead us to different states with different rewards.
- So the value of our state is the average of all discounted rewards that we might get when performing all of the possible actions at the current state.
- Now we have a function that gives us the value of each state. It tells us how good is to be at each one of them.
- Of course we still have to make the computation in order to get a number that represents the value of that state.
- $v(s)$  tells how good to be in state  $s$ , but it does not tell how good to perform action  $a$  while in state  $s$ . This is the purpose of **the Action-Value function**:

$$q_{\pi}(s, a) = \sum_{s', r} p(s', r | s, a) \left[ r + \gamma v_{\pi}(s') \right]$$

# Action Value Function

$$q_{\pi}(s, a) = \sum_{s', r} p(s', r | s, a) \left[ r + \gamma v_{\pi}(s') \right]$$

The explication is simple, we take  $\mathbf{v(s)}$  and instead of performing all actions, we decide to perform only one action.

We no more ask ourselves what is the probability of using action  $\mathbf{a}$  over all possible actions, but we say we will use action  $\mathbf{a}$ .

So the sum of  $\pi(\mathbf{a/s})$  does not apply anymore.

With this logic we reduce  $\mathbf{v(s)}$  from averaging over all possible actions to simply using one selected action, we denote this as  $\mathbf{q(s,a)}$ .

# Action Value Function

Notice that  $q(s,a)$  checks the value of the action at state  $s$  while the values  $v(s')$  of neighboring states are kept unchanged. So in this sense it checks how good this action is in the current state while keeping everything else the same.

It is also easy to notice that  $v(s)$  is the weighted average of  $q(s,a)$  over all possible actions at state  $s$

$$v_{\pi}(s) = \sum_a \pi(a|s) q_{\pi}(s, a)$$

# Policy

The act of selecting an action at each state is called “policy” and is denoted as  $\pi$ .

- some policies are better than others due to the selection of actions over others in one or more states.
- It is important to note that a policy  $\pi$  is better than  $\pi'$  if all  $v(s)$  under  $\pi$  are greater or equal to all  $v(s)$  under  $\pi'$ .
- It follows that in order to **maximize the collected rewards** we have to find the best possible policy, called **optimal policy and denoted  $\pi^*$** .

# Optimal Value Functions and Policy

An optimal value state function  $\mathbf{v}^*(\mathbf{s})$  is a function that gives the maximum value at each state among all policies:

$$v_*(s) = \max_{\pi} v_{\pi}(s), \quad \text{for all } s \in \mathcal{S} \quad \text{where}$$

$$v_{\pi}(s) = \sum_a \pi(a|s) \sum_{s', r} p(s', r | s, a) [r + \gamma v_{\pi}(s')], \quad \text{for all } s \in \mathcal{S}$$

Similarly an optimal action state function  $\mathbf{q}^*(\mathbf{s})$  is the function that gives the maximum  $\mathbf{q}$  value at each state among all policies:

$$q_*(s, a) = \max_{\pi} q_{\pi}(s, a), \quad \text{for all } s \in \mathcal{S} \text{ and } a \in \mathcal{A}(s)$$

it follows that

$$v_*(s) = \max_{a \in \mathcal{A}(s)} q_{\pi_*}(s, a) \quad \text{where} \quad q_{\pi}(s, a) = \sum_{s', r} p(s', r | s, a) [r + \gamma v_{\pi}(s')]$$

$$v_*(s) = \max_a \sum_{s', r} p(s', r | s, a) [r + \gamma v_*(s')]$$

# Optimal Policy

Notice that  $\mathbf{v}(\mathbf{s})$  is the average of values produced by all actions, while  $\mathbf{v}^*(\mathbf{s})$  is the maximum value that one action can produce among all other actions.

$$q_*(s, a) = \sum_{s', r} p(s', r | s, a) \left[ r + \gamma \max_{a'} q_*(s', a') \right]$$

Since  $\mathbf{q}(\mathbf{s}, \mathbf{a})$  is the value produced by a specific action  $\mathbf{a}$  at state  $\mathbf{s}$ ,  $\mathbf{q}^*(\mathbf{s}, \mathbf{a})$  is the value produced by a specific action  $\mathbf{a}$  at state  $\mathbf{s}$ , while selecting maximum  $\mathbf{q}$  values in the other states.

Earlier we said that a policy  $\pi$  is better than another policy  $\pi'$  if it produces higher or equal  $\mathbf{v}(\mathbf{s})$  value at each state:

$$\pi \geq \pi' \text{ if } v_\pi(s) \geq v_{\pi'}(s), \forall s$$

# Optimal Policy

It follows that the optimal policy  $\pi^*$  produces, at each state, higher or equal  $\mathbf{v}(\mathbf{s})$  values than any other policy  $\pi$ .

$$\pi_* \geq \pi \quad \text{if } v_{\pi_*}(s) \geq v_{\pi}(s), \forall s \quad \forall \pi$$

This means that any  $\mathbf{v}(\mathbf{s})$  and  $\mathbf{q}(\mathbf{s}, \mathbf{a})$  following the optimal policy  $\pi^*$  are equal to  $\mathbf{v}^*(\mathbf{s})$  and  $\mathbf{q}^*(\mathbf{s}, \mathbf{a})$  respectively.

*All optimal policies achieve the optimal value function,*

$$v_{\pi_*}(s) = v_*(s)$$

*All optimal policies achieve the optimal action-value function,*

$$q_{\pi_*}(s, a) = q_*(s, a)$$

# How to find the optimal policy $\pi^*$ ?

So the question that remains is, how to find the optimal policy  $\pi^*$  ?

The optimal policy should always return the action that produces  $q^*(s,a)$

$$\pi_*(a|s) = \begin{cases} 1 & \text{if } a = \operatorname{argmax}_{a \in \mathcal{A}} q_*(s, a) \\ 0 & \text{otherwise} \end{cases}$$

- There is always a deterministic optimal policy for any MDP
- If we know  $q^*(s,a)$  it will be very easy to find  $\pi^*$ .

# MDP Example: Grid World

actions = {

1. right 

2. left 

3. up 

4. down 

}

states

★			
			★

Set a negative “reward”  
for each transition  
(e.g.  $r = -1$ )

**Objective:** reach one of terminal states (greyed out) in  
least number of actions

# MDP Example: Grid World

Random Policy

Optimal Policy

# Optimal Policy

Note that the optimal policy is not unique, and this can be easily verified.

Suppose an agent in the Labyrinth has arrived to a state with 3 possible moves (or actions), go left, go right, or go forward. Suppose going forward leads the agent to a dead end, while going left or right will lead the agent to the exit using the same number of steps.

It is clear that there are two optimal policies (not only one) at this state, one that instructs the agent to go left and the other instructs it to go right.

# Markov Decision Process

- At time step  $t=0$ , environment samples initial state  $s_0 \sim p(s_0)$
- Then, for  $t=0$  until done:
  - Agent selects action  $a_t$
  - Environment samples reward  $r_t \sim R(\cdot | s_t, a_t)$
  - Environment samples next state  $s_{t+1} \sim P(\cdot | s_t, a_t)$
  - Agent receives reward  $r_t$  and next state  $s_{t+1}$
- A policy  $\pi$  is a function from  $S$  to  $A$  that specifies what action to take in each state
- **Objective:** find policy  $\pi^*$  that maximizes cumulative discounted reward:  $\sum_{t \geq 0} \gamma^t r_t$

# The optimal policy $\pi^*$

We want to find optimal policy  $\pi^*$  that maximizes the sum of rewards.

How do we handle the randomness (initial state, transition probability...)?

Maximize the **expected sum of rewards!**

Formally:  $\pi^* = \arg \max_{\pi} \mathbb{E} \left[ \sum_{t \geq 0} \gamma^t r_t | \pi \right]$  with  $s_0 \sim p(s_0)$ ,  $a_t \sim \pi(\cdot | s_t)$ ,  $s_{t+1} \sim p(\cdot | s_t, a_t)$

As we see earlier

$$\pi_*(a|s) = \begin{cases} 1 & \text{if } a = \operatorname{argmax}_{a \in \mathcal{A}} q_*(s, a) \\ 0 & \text{otherwise} \end{cases}$$

# Value function and Q-value function

Following a policy produces sample trajectories (or paths)  $s_0, a_0, r_0, s_1, a_1, r_1, \dots$

How good is a state?

The **value function** at state  $s$ , is the expected cumulative reward from following the policy from state  $s$ :

$$V^\pi(s) = \mathbb{E} \left[ \sum_{t \geq 0} \gamma^t r_t \mid s_0 = s, \pi \right]$$

As we see earlier

$$v_\pi(s) = \sum_a \pi(a|s) \sum_{s', r} p(s', r | s, a) \left[ r + \gamma v_\pi(s') \right], \quad \text{for all } s \in \mathcal{S}$$

How good is a state-action pair?

The **Q-value function** at state  $s$  and action  $a$ , is the expected cumulative reward from taking action  $a$  in state  $s$  and then following the policy:

$$Q^\pi(s, a) = \mathbb{E} \left[ \sum_{t \geq 0} \gamma^t r_t \mid s_0 = s, a_0 = a, \pi \right]$$

As we see earlier

$$q_\pi(s, a) = \sum_{s', r} p(s', r | s, a) \left[ r + \gamma v_\pi(s') \right]$$

# Bellman equation

The optimal Q-value function  $Q^*$  is the maximum expected cumulative reward achievable from a given (state, action) pair:

$$Q^*(s, a) = \max_{\pi} \mathbb{E} \left[ \sum_{t \geq 0} \gamma^t r_t \mid s_0 = s, a_0 = a, \pi \right]$$

$Q^*$  satisfies the following **Bellman equation**:

$$Q^*(s, a) = \mathbb{E}_{s' \sim \mathcal{E}} \left[ r + \gamma \max_{a'} Q^*(s', a') \mid s, a \right]$$

**Intuition:** if the optimal state-action values for the next time-step  $Q^*(s', a')$  are known, then the optimal strategy is to take the action that maximizes the expected value of  $r + \gamma Q^*(s', a')$

As we see earlier

$$q_*(s, a) = \sum_{s', r} p(s', r \mid s, a) \left[ r + \gamma \max_{a'} q_*(s', a') \right]$$

The optimal policy  $\pi^*$  corresponds to taking the best action in any state as specified by  $Q^*$

# Solving for the optimal policy

**Value iteration** algorithm: Use Bellman equation as an iterative update

$$Q_{i+1}(s, a) = \mathbb{E} \left[ r + \gamma \max_{a'} Q_i(s', a') | s, a \right]$$

$Q_i$  will converge to  $Q^*$  as  $i \rightarrow \infty$

What's the problem with this?

Not scalable. Must compute  $Q(s, a)$  for every state-action pair. If state is e.g. current game state pixels, computationally infeasible to compute for entire state space!

**Solution:** use a function approximator to estimate  $Q(s, a)$ . E.g. a neural network!

# Solving for the optimal policy: Q-learning

Q-learning: Use a function approximator to estimate the action-value function

$$Q(s, a; \theta) \approx Q^*(s, a)$$

 function parameters (weights)

If the function approximator is a deep neural network => **deep q-learning!**

# Solving for the optimal policy: Q-learning

Remember: want to find a Q-function that satisfies the Bellman Equation:

$$Q^*(s, a) = \mathbb{E}_{s' \sim \mathcal{E}} \left[ r + \gamma \max_{a'} Q^*(s', a') | s, a \right]$$

## Forward Pass

Loss function:  $L_i(\theta_i) = \mathbb{E}_{s, a \sim \rho(\cdot)} \left[ (y_i - Q(s, a; \theta_i))^2 \right]$

where  $y_i = \mathbb{E}_{s' \sim \mathcal{E}} \left[ r + \gamma \max_{a'} Q(s', a'; \theta_{i-1}) | s, a \right]$

Iteratively try to make the Q-value close to the target value ( $y_i$ ) it should have, if Q-function corresponds to optimal  $Q^*$  (and optimal policy  $\pi^*$ )

## Backward Pass

Gradient update (with respect to Q-function parameters  $\theta$ ):

$$\nabla_{\theta_i} L_i(\theta_i) = \mathbb{E}_{s, a \sim \rho(\cdot); s' \sim \mathcal{E}} \left[ r + \gamma \max_{a'} Q(s', a'; \theta_{i-1}) - Q(s, a; \theta_i) \right] \nabla_{\theta_i} Q(s, a; \theta_i)$$

# Training the Q-network: Experience Replay

Learning from batches of consecutive samples is problematic:

- Samples are correlated => inefficient learning
- Current Q-network parameters determines next training samples (e.g. if maximizing action is to move left, training samples will be dominated by samples from left-hand size) => can lead to bad feedback loops

Address these problems using **experience replay**

- Continually update a **replay memory** table of transitions ( $s_t, a_t, r_t, s_{t+1}$ ) as game (experience) episodes are played
- Train Q-network on random minibatches of transitions from the replay memory, instead of consecutive samples

Each transition can also contribute  
to multiple weight updates  
=> greater data efficiency

Experience Replay:  
Sample a random  
minibatch of transitions  
from replay memory  
and perform a gradient  
descent step

# Policy Gradients

What is a problem with Q-learning?

The Q-function can be very complicated!

Example: a robot grasping an object has a very high-dimensional state => hard to learn exact value of every (state, action) pair

But the policy can be much simpler: just close your hand

Can we learn a policy directly, e.g. finding the best policy from a collection of policies?

# Policy Gradients

Formally, let's define a class of parametrized policies:  $\Pi = \{\pi_\theta, \theta \in \mathbb{R}^m\}$

For each policy, define its value:

$$J(\theta) = \mathbb{E} \left[ \sum_{t \geq 0} \gamma^t r_t | \pi_\theta \right]$$

We want to find the optimal policy  $\theta^* = \arg \max_{\theta} J(\theta)$

How can we do this?

Gradient ascent on policy parameters!

# Gradient *ascent*

Gradient *descent* aims at *minimizing* some objective function

$$\theta_j \leftarrow \theta_j - \alpha \frac{\partial}{\partial \theta_j} J(\Theta)$$

Gradient *ascent* aims at *maximizing* some objective function

$$\theta_j \leftarrow \theta_j + \alpha \frac{\partial}{\partial \theta_j} J(\Theta)$$

# REINFORCE Algorithm

Mathematically, we can write:

$$\begin{aligned} J(\theta) &= \mathbb{E}_{\tau \sim p(\tau; \theta)} [r(\tau)] \\ &= \int_{\tau} r(\tau) p(\tau; \theta) d\tau \end{aligned}$$

Where  $r(\tau)$  is the reward of a trajectory  $\tau = (s_0, a_0, r_0, s_1, \dots)$

# REINFORCE Algorithm

Expected reward:  $J(\theta) = \mathbb{E}_{\tau \sim p(\tau; \theta)} [r(\tau)]$

$$= \int_{\tau} r(\tau) p(\tau; \theta) d\tau$$

Now let's differentiate this:  $\nabla_{\theta} J(\theta) = \int_{\tau} r(\tau) \nabla_{\theta} p(\tau; \theta) d\tau$

Intractable! Gradient of an expectation is problematic when  $p$  depends on  $\theta$

However, we can use a nice trick:  $\nabla_{\theta} p(\tau; \theta) = p(\tau; \theta) \frac{\nabla_{\theta} p(\tau; \theta)}{p(\tau; \theta)} = p(\tau; \theta) \nabla_{\theta} \log p(\tau; \theta)$

If we inject this back:

$$\begin{aligned} \nabla_{\theta} J(\theta) &= \int_{\tau} (r(\tau) \nabla_{\theta} \log p(\tau; \theta)) p(\tau; \theta) d\tau \\ &= \mathbb{E}_{\tau \sim p(\tau; \theta)} [r(\tau) \nabla_{\theta} \log p(\tau; \theta)] \end{aligned}$$

Can estimate with  
Monte Carlo sampling

# REINFORCE Algorithm

Can we compute those quantities without knowing the transition probabilities?

We have:  $p(\tau; \theta) = \prod_{t \geq 0} p(s_{t+1} | s_t, a_t) \pi_{\theta}(a_t | s_t)$

Thus:  $\log p(\tau; \theta) = \sum_{t \geq 0} \log p(s_{t+1} | s_t, a_t) + \log \pi_{\theta}(a_t | s_t)$

And when differentiating:  $\nabla_{\theta} \log p(\tau; \theta) = \sum_{t \geq 0} \nabla_{\theta} \log \pi_{\theta}(a_t | s_t)$  Doesn't depend on transition probabilities!

Therefore when sampling a trajectory  $\tau$ , we can estimate  $J(\theta)$  with

$$\nabla_{\theta} J(\theta) \approx \sum_{t \geq 0} r(\tau) \nabla_{\theta} \log \pi_{\theta}(a_t | s_t)$$

$$\begin{aligned} \nabla_{\theta} J(\theta) &= \int_{\tau} (r(\tau) \nabla_{\theta} \log p(\tau; \theta)) p(\tau; \theta) d\tau \\ &= \mathbb{E}_{\tau \sim p(\tau; \theta)} [r(\tau) \nabla_{\theta} \log p(\tau; \theta)] \end{aligned}$$

# Intuition

Gradient estimator:  $\nabla_{\theta} J(\theta) \approx \sum_{t \geq 0} r(\tau) \nabla_{\theta} \log \pi_{\theta}(a_t | s_t)$

## Interpretation:

- If  $r(\tau)$  is high, push up the probabilities of the actions seen
- If  $r(\tau)$  is low, push down the probabilities of the actions seen

Might seem simplistic to say that if a trajectory is good then all its actions were good. **But in expectation, it averages out!**

**However, this also suffers from high variance because credit assignment is really hard. Can we help the estimator?**

# Variance Reduction

Gradient estimator:  $\nabla_{\theta} J(\theta) \approx \sum_{t \geq 0} r(\tau) \nabla_{\theta} \log \pi_{\theta}(a_t | s_t)$

**First idea:** Push up probabilities of an action seen, only by the cumulative future reward from that state

$$\nabla_{\theta} J(\theta) \approx \sum_{t \geq 0} \left( \sum_{t' \geq t} r_{t'} \right) \nabla_{\theta} \log \pi_{\theta}(a_t | s_t)$$

**Second idea:** Use discount factor  $\gamma$  to ignore delayed effects

$$\nabla_{\theta} J(\theta) \approx \sum_{t \geq 0} \left( \sum_{t' \geq t} \gamma^{t'-t} r_{t'} \right) \nabla_{\theta} \log \pi_{\theta}(a_t | s_t)$$

# Variance Reduction: Baseline

**Problem:** The raw value of a trajectory isn't necessarily meaningful. For example, if rewards are all positive, you keep pushing up probabilities of actions.

**What is important then?** Whether a reward is better or worse than what you expect to get

**Idea:** Introduce a baseline function dependent on the state.  
Concretely, estimator is now:

$$\nabla_{\theta} J(\theta) \approx \sum_{t \geq 0} \left( \sum_{t' \geq t} \gamma^{t'-t} r_{t'} - b(s_t) \right) \nabla_{\theta} \log \pi_{\theta}(a_t | s_t)$$

# How to choose the Baseline

$$\nabla_{\theta} J(\theta) \approx \sum_{t \geq 0} \left( \sum_{t' \geq t} \gamma^{t'-t} r_{t'} - b(s_t) \right) \nabla_{\theta} \log \pi_{\theta}(a_t | s_t)$$

A simple baseline: constant moving average of rewards experienced so far from all trajectories

Variance reduction techniques seen so far are typically used in “Vanilla REINFORCE”

# How to choose the Baseline

A better baseline: Want to push up the probability of an action from a state, if this action was better than the **expected value of what we should get from that state**.

Q: What does this remind you of?

A: Q-function and value function!

Intuitively, we are happy with an action  $a_t$  in a state  $s_t$  if  $Q^\pi(s_t, a_t) - V^\pi(s_t)$  is large. On the contrary, we are unhappy with an action if it's small.

Using this, we get the estimator: 
$$\nabla_\theta J(\theta) \approx \sum_{t \geq 0} (Q^{\pi_\theta}(s_t, a_t) - V^{\pi_\theta}(s_t)) \nabla_\theta \log \pi_\theta(a_t | s_t)$$

# Actor-Critic Algorithm

**Problem:** we don't know  $Q$  and  $V$ . Can we learn them?

**Yes**, using Q-learning! We can combine Policy Gradients and Q-learning by training both an **actor** (the policy) and a **critic** (the Q-function).

- The actor decides which action to take, and the critic tells the actor how good its action was and how it should adjust
- Also alleviates the task of the critic as it only has to learn the values of (state, action) pairs generated by the policy
- Can also incorporate Q-learning tricks e.g. experience replay
- **Remark:** we can define by the **advantage function** how much an action was better than expected

$$A^{\pi}(s, a) = Q^{\pi}(s, a) - V^{\pi}(s)$$

# Actor-Critic Algorithm

Initialize policy parameters  $\theta$ , critic parameters  $\phi$

**For** iteration=1, 2 ... **do**

    Sample  $m$  trajectories under the current policy

$\Delta\theta \leftarrow 0$

**For**  $i=1, \dots, m$  **do**

**For**  $t=1, \dots, T$  **do**

$$A_t = \sum_{t' \geq t} \gamma^{t'-t} r_{t'}^i - V_{\phi}(s_t^i)$$

$$\Delta\theta \leftarrow \Delta\theta + A_t \nabla_{\theta} \log(a_t^i | s_t^i)$$

$$\Delta\phi \leftarrow \sum_i \sum_t \nabla_{\phi} ||A_t^i||^2$$

$$\theta \leftarrow \alpha \Delta\theta$$

$$\phi \leftarrow \beta \Delta\phi$$

**End for**

# Recurrent Action Model (RAM)

**Objective:** Image Classification

Take a sequence of “glimpses” selectively focusing on regions of the image, to predict class

- Inspiration from human perception and eye movements
- Saves computational resources => scalability
- Able to ignore clutter / irrelevant parts of image

**State:** Glimpses seen so far

**Action:** (x,y) coordinates (center of glimpse) of where to look next in image

**Reward:** 1 at the final timestep if image correctly classified, 0 otherwise

# Recurrent Action Model (RAM)

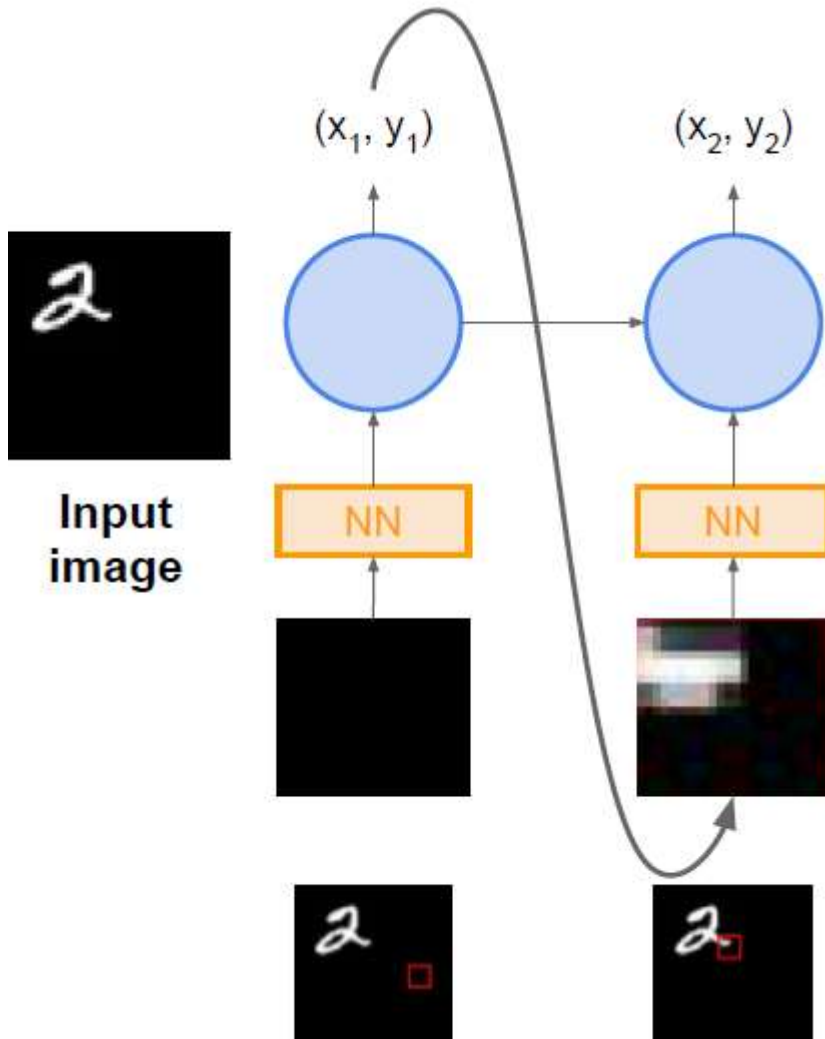

Glimpsing is a non-differentiable operation => learn policy for how to take glimpse actions using REINFORCE  
Given state of glimpses seen so far, use RNN to model the state and output next action

*[Mnih et al. 2014]*
